## HIGHLIGHTS

- ▶ Strong synergic effect between O<sub>3</sub> and TiO<sub>2</sub>/UVA photocatalysis.
- ▶ Three contributions: direct and indirect ozonation, and photocatalytic reactions.
- ▶ Higher quantum yield of photo-generated oxidizing species in TiO<sub>2</sub>/O<sub>3</sub>/UVA.
- ▶ Dissolved O<sub>3</sub> and H<sub>2</sub>O<sub>2</sub> as electron acceptors minimizing the recombination process.

## ABSTRACT

The synergism produced between ozone and TiO<sub>2</sub> black light photocatalytic oxidation of methanol has been studied following the rate of formaldehyde formation during photocatalytic oxidation, ozonation and photocatalytic ozonation experiments. Methanol was selected as a model compound due to its low reaction rate with molecular ozone and its scavenging character for both, free hydroxyl radicals and trapped holes. TiO<sub>2</sub>-P25 was used as photocatalyst and black light blue lamps (emitting with a maximum at 365 nm) as radiation source. The effect of ozone concentration and pH was evaluated. Absorbed light intensity by the photocatalyst was also determined to calculate the quantum yields of photocatalytic reactions. Three main processes need to be considered during photocatalytic ozonation: direct ozone-methanol reaction, indirect ozone reactions and photocatalytic reactions, which allow calculating the quantum yield of photo-generated oxidizing species. The presence of ozone exerts a positive effect in the reaction rate of oxidizing species formation due to light induced reactions also enhancing the quantum yield from 0.34 to 0.80 mol einstein<sup>-1</sup> at pH = 3 (where indirect ozone reactions are negligible). This parameter increased from 0.29 to 3.27 mol einstein<sup>-1</sup> at pH = 7 likely due to indirect ozone reactions that cannot be disregarded. The positive effect of ozone in the photocatalytic induced reactions has been attributed to the reaction of dissolved ozone and hydrogen peroxide (formed upon methanol direct ozonation) as electron acceptors, thus reducing the recombination process on the catalyst surface to some extent. A simplified economic study is also presented.

## 1. Introduction

Wastewater is one of the most important problems in industrialized regions. Many of these effluents contain high concentrations of organic pollutants that must be removed in order to fulfill the

required limits of the increasingly restrictive legislation. In this context, photocatalytic detoxification treatments based on TiO<sub>2</sub> semiconductor have been the focus of numerous investigations in the last 30 years for the destruction of undesirable contaminants in water [1–3]. In heterogeneous photocatalysis, photoinduced holes and electrons in semiconductor particles, through a complex reaction mechanism, give place to highly oxidizing species which play a key role in degradation of organic pollutants. The most

commonly used semiconductor has been polycrystalline powders of titanium dioxide due to unique properties such as chemical stability, safety and low cost [2]. However, its photohole–electron recombination is a serious problem for the development of photocatalytically based technologies since it severely limits the quantum yields achievable [2–4]. Several strategies have been proposed to minimize this problem and increase the process efficiency (ion doping, different semiconductors coupling, using chemical oxidants or combining photocatalysis with other Advanced Oxidation Processes (AOPs) [2]). Among them, the combination of ozone and heterogeneous photocatalysis with TiO<sub>2</sub> (photocatalytic ozonation) has demonstrated to be an efficient treatment enhancing the formation of oxidizing species compared to the single ozonation or photocatalytic processes [5,6].

When a semiconductor (e.g. TiO<sub>2</sub>) is irradiated with a photon of energy greater than its band gap energy an electron/hole pair is formed in the conduction band (CB) and valence band (VB), respectively. These mobile species can migrate to the TiO<sub>2</sub> surface and/or can be readily trapped forming less mobile states (to simplify  $e^-/h^+$  stand for all the forms of holes and electrons).

In addition, these species can give place to the recombination reaction (2):

The nature of trapped holes has been controversially discussed [7,8]. It has been generally assumed that adsorbed water could be photooxidized giving place to surface bounded hydroxyl radicals ( $\cdot\text{OH}_s$ ). However, it has been reported that this reaction was kinetic and thermodynamically hindered [7] and the trapping phenomena by terminal oxygen ions of the TiO<sub>2</sub> lattice ( $\text{O}_{\text{TiO}_2}^{2-}$ ) has been proposed, forming terminal protonated or deprotonated radicals (depending on pH) [9,10]. Regardless the reaction considered, the formation of hydroxyl radicals in the TiO<sub>2</sub> surface can be described:

In addition, oxygen when present on the particle surface, acts as an electron acceptor according to reaction (4):

Superoxide ion radicals ( $\text{O}_2^-$ ) may give place to hydrogen peroxide that can react with TiO<sub>2</sub> electrons and/or additional  $\text{O}_2^-$ , forming free hydroxyl radicals through reactions (5) and (6):

In this complex (but simplified) reaction mechanism, free hydroxyl radicals,  $\cdot\text{OH}$ , and/or trapped holes ( $h^+ = \cdot\text{OH}_s/\cdot\text{O}_s^-$ ), may be responsible of the non-selectively organic matter oxidation and mineralization (reaction (7)), being this process among the most studied AOPs.

When ozone is present, it can react directly and selectively with some organic compounds (i.e. aromatic and substituted aromatic compounds, molecules with unsaturated bonds e.g.  $-\text{C}=\text{C}-$ ,  $-\text{C}\equiv\text{C}-$ ,  $-\text{C}=\text{N}$ ,  $-\text{C}=\text{O}$ , etc.) through different reaction mechanisms (mainly cycloaddition reactions and/or electrophilic substitution) included in “direct ozone reactions” terminology (reaction (8)) [11].

On the other hand, the presence of radical species (i.e. mainly  $\cdot\text{OH}$ ) coming from the decomposition of ozone in water gives place to the non-selectively oxidation of the organic compounds in water (indirect ozone reactions), process that is favored in alkaline media [11]:

The generated ozonide radical ( $\text{O}_3^-$ ) rapidly reacts with  $\text{H}^+$  in the solution to give  $\text{HO}_3\cdot$  radical, which evolves to give  $\text{O}_2$  and  $\cdot\text{OH}$  (reactions (13) and (14)).

The benefits of using the combined process, photocatalytic ozonation, are not only related to the sum of individual processes but also to the fact that the dissolved ozone can readily react with electrons at the TiO<sub>2</sub> surface according to reaction (15) giving place to the ozonide ion radical:

As a consequence, the recombination of electrons and positive holes may be reduced by this reaction (15) and also by reaction (6) due to the presence of higher  $\text{H}_2\text{O}_2$  concentration in the reaction medium, eventually formed during direct ozonation reactions (reaction (8)) [12–14]. With this reaction scheme a synergistic effect between ozone and semiconductor photocatalysis is expected due to the larger amount of oxidizing species formed (hydroxyl radicals, bounded hydroxyl radicals and/or positive holes). This has been observed for the photocatalytic ozonation of several organic compounds in water [2,5,6,15–19].

Some of the target compounds subjected to photocatalytic ozonation were complex molecules that present high direct ozone–organic rate constants and/or also complicated reaction pathways involving several steps with different intermediate species [5,16,19]. This makes difficult to analyze the reaction mechanism, the species involved in the oxidation steps and/or the synergistic effect between ozone and photocatalysis. In that sense, it would be interesting to test the photocatalytic ozonation process using small and refractory organic compounds to direct ozone reactions.

In this work methanol has been selected due to its known scavenging character of hydroxyl radicals ( $k_{\text{OH}} = 9.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ , [20]) and that also has been commonly used to test the photocatalytic efficiency of several TiO<sub>2</sub> materials since it reacts with photo-generated holes [9,10,21–25]. In addition, methanol–ozone direct reaction takes place at slow reaction rate ( $k_{\text{O}_3} = 0.024 \text{ M}^{-1} \text{ s}^{-1}$ ) [26]. Therefore, it is expected that under appropriate experimental conditions, the formaldehyde evolution (formaldehyde is the first product of methanol oxidation) gives information about the production rate of oxidizing species (different from  $\text{O}_3$ ). The aim of this work was then to evaluate the production of photo-generated oxidizing species (hydroxyl radicals and positive holes) using methanol as target compound comparing both, photocatalytic oxidation and photocatalytic ozonation, to determine the true quantum yield of photocatalytic reactions, and to state the synergy degree between ozone and irradiated semiconductor during photocatalytic ozonation. To our knowledge the determination of the quantum yield of photo-generated oxidizing species production in photocat-

alytic ozonation has not been studied before with any target compound.

## 2. Experimental section

### 2.1. Experimental set-up and oxidation/ozonation procedure

Ozonation, photocatalytic oxidation and photocatalytic ozonation experiments were carried out in a 1 L slurry cylindrical reactor equipped with magnetic stirring and inlets for measuring temperature, feeding the gas (oxygen or ozone-oxygen) through a porous plate situated at the reactor bottom, sampling port and outlet for the non-absorbed gas. In photocatalytic experiments, the reactor was illuminated with 2 black light blue (UVA radiation) fluorescent lamps (15 W each, from HQPower) placed inside a black box.

The reactor was charged with an aqueous solution containing methanol (2 M, CH<sub>3</sub>OH HPLC grade from Panreac) and TiO<sub>2</sub> (0.5 g L<sup>-1</sup>, Degussa P25, in catalytic experiments). Initial pH was set to 3 with HClO<sub>4</sub>, pH = 7 with NaOH or buffered at pH = 7 with H<sub>3</sub>PO<sub>4</sub> (30 mM) and NaOH (from Panreac). In photocatalytic experiments, the reactor was then exposed to the radiation (lamps were turned on 30 min before to stabilize). In ozonation experiments a mixture of ozone-oxygen gas (30 L h<sup>-1</sup>, 10–30 mg L<sup>-1</sup>) was also continuously fed to the reactor. Ozone was generated from pure oxygen in a Sander laboratory ozonator. Temperature was maintained at 25 °C during the reaction time. Reaction samples were withdrawn from the reactor at regular intervals for 60 min reaction time, and then filtered through syringe PET membrane filters (Chromafil Xtra, 0.20 μm). The evolution of the reaction was followed through the determination of formaldehyde (primary product of methanol oxidation), hydrogen peroxide, dissolved ozone concentration, ozone concentration in the outlet gas and pH.

Formaldehyde was determined by the Nash method [27], based on the Hantzsch reaction. In this assay, 2 mL of reagent (0.2 mL of acetylacetone (Sigma–Aldrich), 3 mL of acetic acid (Panreac) and 25 g of ammonium acetate (Fluka) in 100 mL of water) are mixed with 5 mL of the sample, heated for 30 min at 50 °C in the dark [28]. Spectrophotometric measurements were carried out at 412 nm ( $\epsilon = 7890 \text{ M}^{-1} \text{ cm}^{-1}$ ) using a Helios- $\alpha$  Thermo Spectronic spectrophotometer. Hydrogen peroxide concentration was determined through the cobalt/bicarbonate method [29], at 260 nm ( $\epsilon = 26645 \text{ M}^{-1} \text{ cm}^{-1}$ ) using a Helios- $\alpha$  spectrophotometer. Dissolved ozone concentration was measured by following the method proposed by Bader and Hoigné [30] based on the decoloration of a 5,5,7 indigotrisulphonate solution ( $\lambda = 600 \text{ nm}$ , Helios- $\alpha$  spectrophotometer,  $\epsilon = 20000 \text{ M}^{-1} \text{ cm}^{-1}$ ). Ozone in the gas phase was monitored by means of an Anseros Ozomat ozone analyzer, based on the absorbance at 254 nm.

### 2.2. Photon fluxes determination

Ferrioxalate actinometry [31] was used to determine the incident photon flux,  $I_0$ , in the photoreactor, that was found to be  $2.66 \times 10^{-5} \text{ einstein min}^{-1}$ . In these experiments the Fe(II) concentration was followed by the o-fenantroline method [32] using a Helios- $\alpha$  spectrophotometer at 510 nm ( $\epsilon = 11023 \text{ M}^{-1} \text{ cm}^{-1}$ ). The photon flux,  $I_a$ , absorbed by the catalyst was estimated through the determination of the quantum yield of formaldehyde generation in the photoreactor. This was obtained by applying the protocol of Serpone and Salinaro [33] for the photocatalytic oxidation of methanol, analyzing the formaldehyde evolution under the following operating conditions: methanol concentration from 0.5 to 2 M, TiO<sub>2</sub> concentration from 0.025 to 3 g L<sup>-1</sup>, pH<sub>0</sub> = 7, pH = 7 (buffered) and pH<sub>0</sub> = 3 (adjusted with NaOH, phosphate buffered or adjusted with HClO<sub>4</sub>, respectively) and oxygen saturated solution with

30 L h<sup>-1</sup> gas flow rate. The evolution of the reaction was followed as explained in the previous section. For comparative purposes, additional photocatalytic oxidation experiments were carried out using formic acid 0.01 M as target compound (0.5 g L<sup>-1</sup> TiO<sub>2</sub>, pH<sub>0</sub> = 3). Formic acid was determined following the evolution of the CO<sub>2</sub> formed by measuring the total organic carbon (TOC) remaining in the solution using a TOC-V<sub>SCH</sub> analyzer from Shimadzu.

## 3. Results and discussion

### 3.1. Absorbed photon flux

The determination of the absorbed photon flux by the catalyst is a key issue in heterogeneous photocatalytic reactions that serves to calculate the quantum yield of the reaction according to the following equation:

$$\phi_i = \frac{\text{reacted molecules}}{\text{absorbed photons}} = \frac{r_i}{I_a} \left( \frac{\text{mol } i}{\text{einstein}} \right) \quad (16)$$

The radiant energy used in a photocatalytic reaction (absorbed,  $I_a$ ) is generally lower than that impinging on the reacting system ( $I_0$ ) due to the light scattered or reflected by the suspended catalyst in the dispersion. The absorbed light intensity has been usually calculated by applying the radiation transfer equation (RTE) to the reaction system [34–38] or experimentally determined by means of the measurement of the light transmission through a photocatalyst suspension [39].

In this work, we have indirectly calculated the absorbed photon flow by using the protocol of Serpone and Salinaro [33] to determine the quantum yield of the methanol oxidation reaction (formaldehyde formation) under our experimental conditions.

Methanol photocatalytic oxidation gives place to formaldehyde as primary oxidation product according to reactions (17) and (18):

where either holes ( $h^+$ ) and free hydroxyl radicals ( $\cdot\text{OH}$ ) may participate, forming also superoxide ion radical ( $\text{O}_2^{\cdot-}$ ) or hydroperoxide radical (acidic pH) ( $\text{HO}_2\cdot$ ). Fig. 1 shows the time-evolution of CHOH formation under different experimental conditions. It was nearly

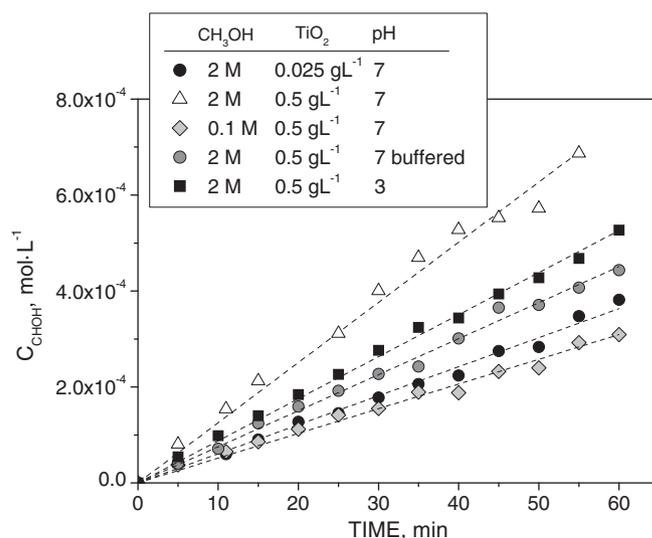

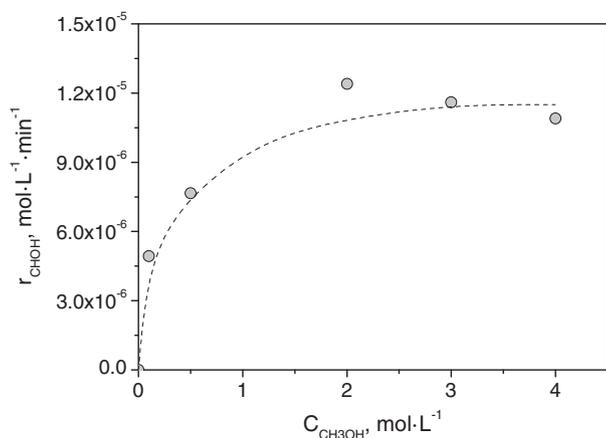

Fig. 1. Time-evolution of formaldehyde formation during methanol photocatalytic oxidation experiments. Conditions:  $T = 25 \text{ }^\circ\text{C}$ ,  $Q_g = 30 \text{ L h}^{-1} (\text{O}_2)$ .

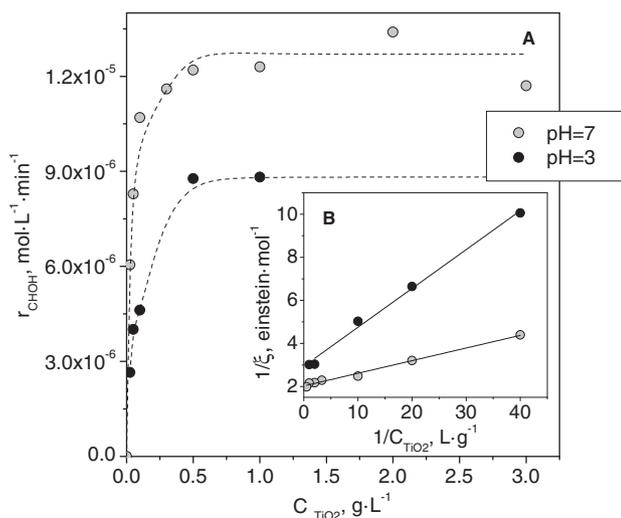

**Fig. 2.** Rate of formaldehyde formation versus methanol concentration in photocatalytic oxidation experiments. Conditions: pH = 7,  $T = 25\text{ }^{\circ}\text{C}$ ,  $C_{\text{TiO}_2} = 2\text{ g L}^{-1}$ ,  $Q_g = 30\text{ L h}^{-1}(\text{O}_2\text{ or O}_3/\text{O}_2)$ .

linear throughout the range of conditions used. The rate of CHO H formation reached a plateau around 2 M methanol, as can be seen in Fig. 2. This concentration was then used for the experiments with different TiO<sub>2</sub> concentration. At this CH<sub>3</sub>OH concentration, formaldehyde is not expected to be significantly oxidized since oxidizing species will mainly react with the former. In fact, taking into account the kinetic constants of methanol and formaldehyde with hydroxyl radicals ( $9.7 \times 10^8$  and  $1 \times 10^9\text{ M}^{-1}\text{ s}^{-1}$  [20], respectively) the formaldehyde formation rate with 2 M methanol was 1940 times higher than formaldehyde oxidation rate (using a generic concentration about  $10^{-3}\text{ M}$  similar to CHO H concentrations observed in this work) proving that formaldehyde oxidation could be negligible in the overall reaction rate. The calculated reaction rates of formaldehyde formation at different TiO<sub>2</sub> loading defines a plateau from  $0.5\text{ g L}^{-1}$  as depicted in Fig. 3A. This behavior can be well described through the following equation:

$$\xi = \frac{\xi_{\text{lim}} a C_{\text{TiO}_2}}{\xi_{\text{lim}} + a C_{\text{TiO}_2}} = \frac{r_{\text{CHOH}}}{I_0} \quad (19)$$

where photonic efficiencies are calculated employing the relationship  $\xi = r_{\text{CHOH}}/I_0$ . The quantum yield of formaldehyde formation

**Fig. 3.** (A) Rate of formaldehyde formation versus TiO<sub>2</sub> loading in methanol photocatalytic oxidation experiments. (B): Fitting results of linearized Eq. (19). Conditions: pH = 7 and 3,  $T = 25\text{ }^{\circ}\text{C}$ ,  $Q_g = 30\text{ L h}^{-1}(\text{O}_2\text{ or O}_3/\text{O}_2)$ .

( $\varphi_{\text{CHOH}}$ ) was determined from the limiting photonic efficiency ( $\xi_{\text{lim}}$ ) at high TiO<sub>2</sub> loadings. At these conditions it has been reported that  $\xi_{\text{lim}} = \varphi$  [33]. Fig. 3B shows fitting results of linearized Eq. (19). The quantum yield calculated for formaldehyde formation at pH<sub>0</sub> = 7 (non-buffered) was  $\varphi_{\text{CHOH-pH7}} = 0.48\text{ mol einstein}^{-1}$ . The pH value did not change significantly (pH<sub>f</sub> = 6.7). The corresponding absorbed light intensity at different TiO<sub>2</sub> loadings are summarized in Table 1 together with the integrated absorption fraction over the wavelength used here,  $F_s = I_a/I_0$ . From  $0.5\text{ g L}^{-1}$  TiO<sub>2</sub> onward, the P25 catalyst presented an absorption fraction higher than 90%. On the other hand, in experiments carried out at pH = 7 (phosphate buffered solution), the reaction rate of formaldehyde formation was lower than in the previous case at the same operating conditions (catalyst loading, methanol concentration) as can also be observed in Fig. 1 and Table 1. This can be due to phosphate adsorption onto the titania surface [40,41], that can compete for adsorption sites with methanol and/or react with oxidizing species formed at the catalyst surface (e.g. with hydroxyl radicals,  $k_{\text{OH-PO}_4^{3-}} = 1 \times 10^7\text{ M}^{-1}\text{ s}^{-1}$ ,  $k_{\text{OH-HP}_4\text{O}_4^{2-}} = 1.5 \times 10^5\text{ M}^{-1}\text{ s}^{-1}$ ,  $k_{\text{OH-H}_2\text{PO}_4^-} = 2 \times 10^4\text{ M}^{-1}\text{ s}^{-1}$ ,  $k_{\text{OH-H}_3\text{PO}_4} = 2.7 \times 10^6\text{ M}^{-1}\text{ s}^{-1}$  [20]), although this second point could be disregarded due to the great excess of methanol (2 M CH<sub>3</sub>OH against 30 mM H<sub>3</sub>PO<sub>4</sub>). Since phosphates do not absorb the black light used, it is expected that the absorbed light intensity,  $I_a$ , do not change significantly compared to the non-buffered experiments at pH = 7.

On the other hand, it is known that the size of the TiO<sub>2</sub> aggregates in aqueous solution depends on the pH value and therefore, could affect the intensity of light absorbed by the photocatalyst [2]. Thus, additional photocatalytic oxidation experiments with  $0.025\text{--}1\text{ g L}^{-1}$  TiO<sub>2</sub> were carried out at pH<sub>0</sub> = 3 to calculate both, the quantum yield ( $\varphi_{\text{CHOH-pH3}}$ ) and the absorbed photon flow at this pH value. Firstly, the pH value did not significantly change during the reaction time. It was observed that the rate of formaldehyde formation at pH<sub>0</sub> = 3 was quite lower than at pH<sub>0</sub> = 7 (non-buffered) at the same catalyst loading (see Fig. 1). These results have also been plotted in Fig. 3A whereas Fig. 3B shows fitting results of linearized Eq. (19) for experiments at pH<sub>0</sub> = 3. The quantum yield calculated was  $\varphi_{\text{CHOH-pH3}} = 0.34\text{ mol einstein}^{-1}$ . The absorbed light intensity calculated was somewhat higher than at pH = 7 in experiments at the same catalyst loading (Table 1), according to the lower aggregates size expected at lower pH. The lower reaction rates and quantum yield observed could be attributed to the stabilization of the  $\cdot\text{O}_2\text{CH}_2\text{OH}$  radical at acidic pH [42] and/or to the presence of ClO<sub>4</sub><sup>-</sup> ions (HClO<sub>4</sub> used to set pH = 3) that can be absorbed onto the catalyst surface [43]. Previously, Du and Rabani [42] showed that quantum yields of formaldehyde formation during photocatalytic oxidation of methanol with a TiO<sub>2</sub> catalyst fell down from 0.2 to 0.05 mol einstein<sup>-1</sup> at pH = 7 and pH = 3, respectively, whereas when comparing the quantum yield of CO<sub>2</sub> formation during photocatalytic oxidation of formic acid at pH = 3, the value was quite similar to that found for the methanol system at pH = 7. This was explained on the basis of the stabilization of the  $\cdot\text{O}_2\text{CH}_2\text{OH}$  radical at acidic pH when using methanol. However, our experiments carried out at pH = 3 with formic acid 0.01 M (high enough to reach constant reaction rate independent of formic acid concentration [42]) led to the results summarized in Table 1, where the photonic efficiency calculated for CO<sub>2</sub> formation was  $0.26\text{ mol einstein}^{-1}$ , quite similar (even lower) than the value obtained in the methanol system. These results seem to be pointed out that the stabilization of the  $\cdot\text{O}_2\text{CH}_2\text{OH}$  radical at pH = 3 is not the main responsible of the decrease observed in the quantum yield at this pH value under the operating conditions used here and, therefore, we have used also methanol at pH = 3 as model compound.

Finally, under the same experimental conditions,  $I_a$  is not expected to significantly change in presence of ozone during photocatalytic ozonation experiments since O<sub>3</sub> does not absorb black

light radiation ( $\lambda = 365$  nm). The calculated  $I_a$  values were used to determine the quantum yields for photocatalytic ozonation processes for comparative purposes.

### 3.2. Photocatalytic oxidation versus photocatalytic ozonation

To compare photocatalytic oxidation behavior versus photocatalytic ozonation, similar experiments were carried out at the same operating conditions of methanol concentration, gas flow rate, radiation and pH, but feeding ozone to the system. At 2 M methanol concentration used here, also in ozonation and photocatalytic ozonation experiments, formaldehyde ozonation is not expected. According to the kinetic constants of methanol and formaldehyde with O<sub>3</sub> (0.024 and 0.10 M<sup>-1</sup> s<sup>-1</sup> [26], respectively) and the concentration of both compounds, the formaldehyde formation rate with 2 M methanol was almost 500 times higher than the formaldehyde ozonation (using a generic concentration about 10<sup>-3</sup> M similar to CHO<sub>H</sub> concentrations observed in this work) proving that formaldehyde ozonation could be neglected in the overall reaction rate.

The comparison of formaldehyde formation during photocatalytic oxidation (TiO<sub>2</sub>/O<sub>2</sub>/UVA) and photocatalytic ozonation (TiO<sub>2</sub>/O<sub>3</sub>/UVA) of methanol is presented in Fig. 4A. Also, for comparative purposes single ozonation (O<sub>3</sub>) and photolytic ozonation results (i.e. irradiated O<sub>3</sub> without TiO<sub>2</sub>, O<sub>3</sub>/UVA) have been plotted. These experiments were carried out at pH = 3 to minimize indirect ozone reactions. This pH value did not significantly change throughout the reaction time. As expected, ozonation and photolytic ozonation gave place to similar formaldehyde evolution since ozone does not absorb black light radiation. On the other hand, the results observed for photocatalytic oxidation are also quite similar to the ozone process. The highest rate of formaldehyde formation was found during photocatalytic ozonation. Reaction rates were calculated through the slope of the CHO<sub>H</sub> concentration–time evolution and are displayed in Table 2. A synergistic effect between ozone and the irradiated TiO<sub>2</sub> can be observed during TiO<sub>2</sub>/O<sub>3</sub>/UVA treatment where the reaction rate is almost twice higher than the sum of the reaction rates of individual process (2.91 × 10<sup>-5</sup> M min<sup>-1</sup> versus 1.89 × 10<sup>-5</sup> M min<sup>-1</sup>, respectively).

The accumulation of important concentrations of hydrogen peroxide was also observed during ozonation experiments. Results are plotted in Fig. 4B. As can be seen, during photocatalytic oxidation of methanol small amounts of hydrogen peroxide could be detected whereas during single ozonation and photolytic ozonation, the evolution of hydrogen peroxide is comparable to the formaldehyde formation. This is explained on the basis of ozone–methanol

**Fig. 4.** Time-evolution of formaldehyde (A) and hydrogen peroxide (B) concentrations during ozonation and photocatalytic oxidation/ozonation experiments. Conditions: pH = 3,  $T = 25$  °C,  $C_{TiO_2} = 0.5$  g L<sup>-1</sup>,  $C_{O_3\text{inlet}} = 10$  mg L<sup>-1</sup>,  $Q_g = 30$  L h<sup>-1</sup> (O<sub>2</sub> or O<sub>3</sub>/O<sub>2</sub>).

direct reaction which gives place to hydrogen peroxide [44] according to:

It is noticeable that hydrogen peroxide concentration was much lower in the photocatalytic ozonation experiment likely due to the consumption of H<sub>2</sub>O<sub>2</sub> through reaction (6) (H<sub>2</sub>O<sub>2</sub> – e<sub>aq</sub><sup>-</sup> reaction:  $k = 1.1 \times 10^{10}$  M<sup>-1</sup> s<sup>-1</sup> [20]). This reaction will also enhance the generation of hydroxyl radicals improving methanol oxidation.

In addition, dissolved ozone was measured during all the ozonation experiments. The concentration was nearly constant at 7.5 × 10<sup>-6</sup> M and 4.5 × 10<sup>-6</sup> M during ozonation and photocatalytic ozonation, respectively. Also the ozone concentration in the gas phase in the reactor outlet was lower during photocatalytic

<sup>a</sup> Buffered solution ( $\text{H}_3\text{PO}_4$  30 mM).

<sup>b</sup> It coincides with  $r_{\text{CHOH}}$  for single ozonation experiments at pH = 3.

<sup>c</sup> Calculated from ozonation experiments by means of the difference between  $r_{\text{CHOH}} - r_{\text{O}_3}$ .

<sup>d</sup> Calculated by means of the difference between  $r_{\text{CHOH}} - r_{\text{O}_3} - r_{\text{OH-O}_3}$ .

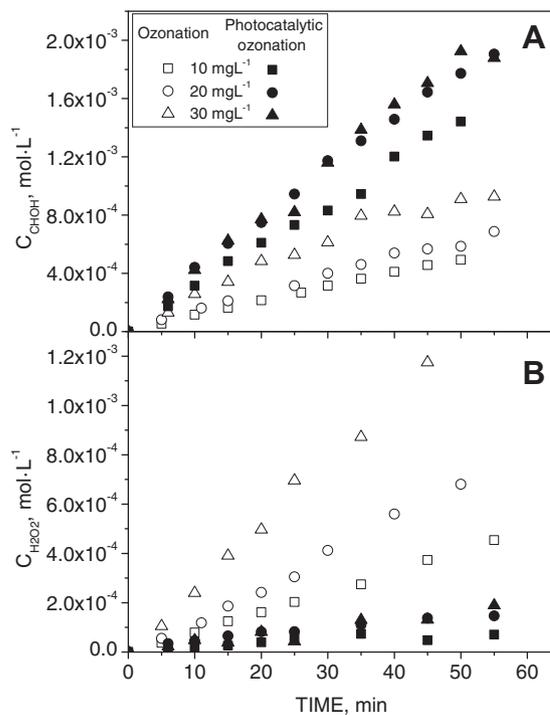

ozonation ( $5.0 \text{ mg L}^{-1}$ ) than during ozonation ( $6.5 \text{ mg L}^{-1}$ ). The lower values found during photocatalytic ozonation suggests that  $\text{O}_3$  is also been consumed through reaction (15) ( $\text{O}_3 - e_{\text{aq}}^-$  reaction:  $k = 3.6 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ , which is also higher than the one of  $\text{O}_2 - e_{\text{aq}}^-$  reaction:  $k = 1.9 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$  [20]), improving methanol oxidation rate due to the generation of additional hydroxyl radicals.

Therefore, taking into account the slow reaction rate of direct methanol ozonation and the negligible contribution of ozone decomposition at the pH value used here, the synergism observed may be related to the reaction of dissolved ozone and hydrogen peroxide as electron acceptors to produce  $\cdot\text{OH}$  radicals, thus avoiding in some extent the recombination reactions on the  $\text{TiO}_2$  catalyst.

### 3.2.1. Influence of ozone concentration

The influence of ozone concentration in the feeding gas during photocatalytic ozonation of methanol was studied at pH = 3. Results of formaldehyde and hydrogen peroxide formation with time are depicted in Fig. 5A and B, respectively. Also, for the sake of comparison, single ozonation results varying the ozone gas concentration have been plotted. It can be observed that ozone concentration exerts a positive effect on the methanol oxidation rate (formaldehyde formation), compared to the ozone free experiments (see also Fig. 4A) both in single ozonation and photocatalytic ozonation, although the effect is less important when increasing the ozone gas concentration. Reaction rates of formaldehyde formation have been calculated and are shown in Table 2. The increase of formaldehyde formation rate is proportional to the increasing ozone concentration in single ozonation experiments whereas it is more important from 10 to 20  $\text{mg L}^{-1}$  of ozone than from 20 to 30  $\text{mg L}^{-1}$  in photocatalytic ozonation. This behavior has been observed before during photocatalytic ozonation process [19] and has been attributed to complex Langmuir kinetics for substances that absorb and react on the semiconductor surface.

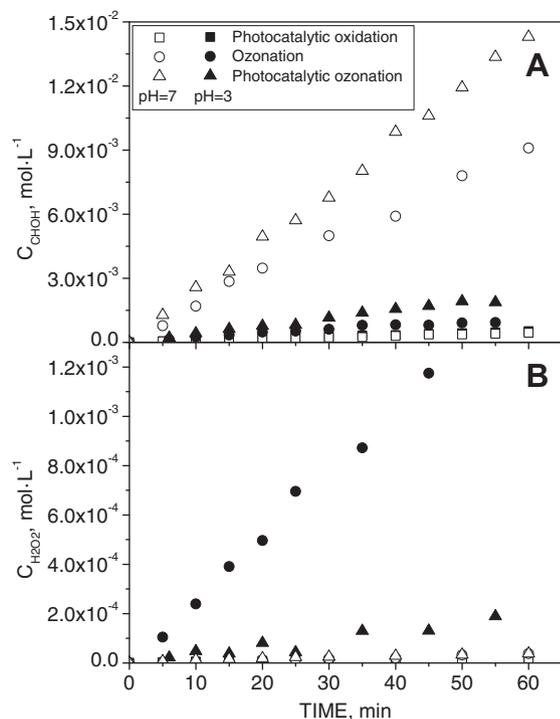

Regarding the evolution of  $\text{H}_2\text{O}_2$  during the experiments at different  $\text{O}_3$  concentration (Fig. 5B), it can be observed that  $\text{H}_2\text{O}_2$ , formed mainly from direct ozonation of methanol, is further accumulated during ozonation treatment while is not in the photocatalytic ozonation process and regardless of the ozone concentration. The latter is likely due to the consumption of  $\text{H}_2\text{O}_2$  in the photocatalytic process through reaction (6). Despite this, a positive effect of ozone concentration is observed on the evolution of  $\text{H}_2\text{O}_2$  in both treatments, more pronounced during ozonation.

**Fig. 5.** Time-evolution of formaldehyde (A) and hydrogen peroxide (B) concentrations during methanol ozonation and photocatalytic ozonation experiments. Conditions: pH = 3,  $T = 25^\circ\text{C}$ ,  $C_{\text{TiO}_2} = 0.5 \text{ g L}^{-1}$ ,  $C_{\text{O}_3, \text{inlet}} = 10, 20, 30 \text{ mg L}^{-1}$ ,  $Q_g = 30 \text{ L h}^{-1}$  ( $\text{O}_3/\text{O}_2$ ).

### 3.2.2. Influence of pH

Previous experiments have been carried out at pH = 3 to minimize ozone decomposition reaction and, thus, avoiding indirect methanol-ozone oxidation reaction. However, pH plays a crucial role during ozonation processes. Results of photocatalytic oxidation, ozonation and photocatalytic ozonation of  $\text{CH}_3\text{OH}$  at pH = 3 and pH = 7 (buffered solution) are compared in Fig. 6. Regarding CHO formation, slight differences were observed in Fig. 6A for photocatalytic oxidation reaction at pH = 3 and pH = 7 as commented in the previous section. Nevertheless, when ozone is present, a large increase in the rate of CHO formation is observed at pH = 7 respect to pH = 3. During single ozonation experiments

**Fig. 6.** Time-evolution of formaldehyde (A) and hydrogen peroxide (B) concentrations during methanol ozonation and photocatalytic oxidation/ozonation experiments. Conditions: pH = 3, 7,  $T = 25\text{ }^{\circ}\text{C}$ ,  $C_{\text{TiO}_2} = 0.5\text{ g L}^{-1}$ ,  $C_{\text{O}_3\text{inlet}} = 30\text{ mg L}^{-1}$ ,  $Q_g = 30\text{ L h}^{-1}$  ( $\text{O}_2$  or  $\text{O}_3/\text{O}_2$ ).

the formaldehyde formation rate increased around 8 times (from  $1.97 \times 10^{-5}$  to  $1.55 \times 10^{-4}\text{ M min}^{-1}$ , see Table 2). Direct ozone-methanol reaction is not affected by pH modifications since  $\text{CH}_3\text{OH}$  does not dissociate at the studied pH range [26]; as a consequence, this behavior is related to ozone decomposition reactions (9)–(14) that are produced at neutral pH to generate  $\cdot\text{OH}$  radicals in the reaction medium. In this line, lower dissolved ozone concentration has been detected at pH = 7 ( $8 \times 10^{-7}\text{ M}$  and  $1 \times 10^{-6}\text{ M}$  in ozonation and photocatalytic ozonation, respectively) compared to pH = 3 ( $8.2 \times 10^{-6}\text{ M}$  and  $6.1 \times 10^{-6}\text{ M}$  in ozonation and photocatalytic ozonation, respectively). Also, ozone concentration in the gas phase at the reactor outlet has been observed to decrease with pH increase from 3 to 7 (from 15 at pH 3 to 10  $\text{mg L}^{-1}$  at pH 7 in ozonation, and from 11 at pH 3 to 6  $\text{mg L}^{-1}$  at pH 7 in photocatalytic ozonation runs). This corroborates a higher consumption of ozone at neutral pH likely due to its faster decomposition.

In addition, hydrogen peroxide formed upon direct ozone-methanol reaction can be dissociated (reaction (21),  $pK = 11.3$ ), promoting reaction (10) to some extent:

In fact, hydrogen peroxide concentrations detected at pH = 7 were fairly lower than at pH = 3 (see Fig. 6B), indicating that  $\text{H}_2\text{O}_2$  is consumed during the single ozonation process. Another fact that can affect the ozonation mechanism due to the pH value is that the hydroperoxil radical formed upon methanol- $\cdot\text{OH}$  oxidation ( $\text{HO}_2\cdot$ ) will be on its dissociated form ( $\text{O}_2^{\cdot-}$ ) at neutral pH (reaction (11),  $pK = 4.8$ ), then it also participates in the reaction mechanism of ozone decomposition.

The increase of formaldehyde formation rate observed was more significant in photocatalytic ozonation due to the formation of higher concentration of oxidizing species at the photocatalyst surface according to the reaction scheme described above. At pH = 7 and  $30\text{ mg L}^{-1}$  of ozone inlet concentration, the synergistic

effect is clearly observed in the reaction rate at this pH value (see Table 2), where the sum of ozone and photocatalytic oxidation rates was  $1.62 \times 10^{-4}\text{ M min}^{-1}$  fairly lower than that of photocatalytic ozonation ( $2.38 \times 10^{-4}\text{ M min}^{-1}$ ). Therefore, an increment in the pH value exerts a positive effect on the photocatalytic ozonation reaction due to the formation of species that favor the ozone decomposition in water.

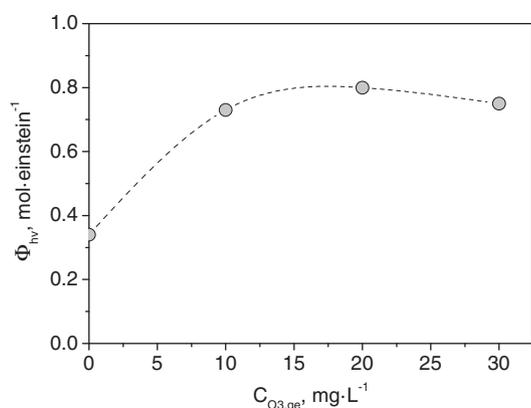

### 3.2.3. Synergistic effect and quantum yield of photocatalytic induced reactions

From the previous experimental results, different contributions to the rate of formaldehyde formation have been calculated. On one hand, when single ozonation experiments were carried out at pH = 3, the contribution of  $\text{O}_3$  indirect reactions ( $r_{\text{OH-O}_3}$ ) can be neglected and therefore, the observed reaction rate at this pH would only be due to the direct ozone-methanol reaction ( $r_{\text{O}_3}$ ). This was extrapolated to photocatalytic ozonation considering the same contribution of ozone-methanol direct reaction than in the absence of light. Additionally, for photocatalytic treatments, another contribution needs to be considered due to the photogenerated oxidizing species (i.e.  $\text{h}^+$  and  $\cdot\text{OH}$  from reactions (1)–(6), and (15)) apart from the direct or indirect ozonation mechanism. This contribution, named  $r_{\text{hv}}$ , is the observed rate of  $\text{CHOH}$  formation in photocatalytic oxidation, and was calculated as the difference between the observed reaction rate  $r_{\text{CHOH}}$  and the direct-indirect ozone reactions in photocatalytic ozonation. On the other hand, when reactions were carried out at pH = 7, the contribution of indirect ozone reactions become very important. In this case, this contribution was calculated by subtracting the ozone-direct reaction rate (calculated at pH = 3 at the same operating conditions) to the observed reaction rate of formaldehyde formation during single ozonation experiments. Also, these results were extrapolated to photocatalytic ozonation at pH = 7. The different contributions to the global reaction rate of formaldehyde formation during methanol oxidation have been summarized in Table 2. Regarding the photocatalytic contribution, it is noticeable the increase underwent in the light induced reaction rate when ozone was present compared to the one of photocatalytic oxidation at the same operating conditions. The degree of enhancement produced as a consequence of  $\text{O}_3$  was calculated as follows:

$$E = \frac{r_{\text{hv}}(\text{TiO}_2/\text{O}_3/\text{UVA}) - r_{\text{hv}}(\text{TiO}_2/\text{O}_2/\text{UVA})}{r_{\text{hv}}(\text{TiO}_2/\text{O}_2/\text{UVA})} \cdot 100 (\%) \quad (22)$$

Table 2 shows the values obtained for all the photocatalytic ozonation experiments. The enhancement observed in the photocatalytic contribution increased from ca 53% to 57% when increasing ozone concentration in the feeding effluent at pH = 3, although slight differences were observed when using 20 or  $30\text{ mg L}^{-1}$   $\text{O}_3$  as commented in the previous section. The highest enhancement was observed at pH = 7 with  $30\text{ mg L}^{-1}$  of ozone. This parameter can be considered as a real evidence of the synergism produced between ozone and irradiated  $\text{TiO}_2$ .

At the experimental conditions used (high excess of  $\text{CH}_3\text{OH}$ ), the reaction rate calculated for the photocatalytic contribution ( $r_{\text{hv}}$ ) can be well considered as the reaction rate of oxidizing species formation due to light induced reactions. Therefore, the quantum yield of these reactions (light induced ones) can be calculated taking into account the absorbed light intensity at the operating conditions used (see Table 1). The calculated quantum yields of ( $\phi_{\text{hv}}$ ) for photocatalytic oxidation and photocatalytic ozonation processes are presented in Table 2. The quantum yield of photogenerated species formation in photocatalytic ozonation at pH = 3 was found to be increased twice and near triple times the value observed for photocatalytic oxidation as ozone concentration increased. Quantum yield reached a plateau at high ozone

**Fig. 7.** Evolution of quantum yield of oxidizing species formation through light induced reactions with ozone inlet concentration. Conditions: pH = 3,  $T = 25^\circ\text{C}$ ,  $C_{TiO_2} = 0.5\text{ g L}^{-1}$ ,  $Q_g = 30\text{ L h}^{-1}$  ( $O_2$  or  $O_3/O_2$ ).

concentrations, as can also be observed in Fig. 7 where the evolution of the quantum yield with ozone concentration has been depicted. This trend suggests that a limiting reaction rate has been reached in the system due to the reaction of hydroxyl radicals with  $O_3$ . Sun and Bolton [21] also observed this behavior while studying the photocatalytic oxidation of methanol with the addition of hydrogen peroxide as an electron acceptor. On the other hand, the highest improvement of the quantum yield has been observed in the experiment of photocatalytic ozonation at pH = 7 reaching a value near 3 photogenerated oxidizing species per absorbed photon.

The maximum quantum yield of formaldehyde formation expected during photocatalytic oxidation is  $\phi_{CHOH,max} = \phi_{hv,max} = 1.5\text{ mol Einstein}^{-1}$ , according to the reaction mechanism proposed where 2 photons are needed to produce 3 oxidizing species (i.e. holes and/or hydroxyl radicals) taking into account also the radical  $O_2^-/HO_2$  formed from  $CH_3OH$  oxidation [6]. This maximum becomes even greater ( $\phi_{hv,max-O_3} = 2 - 3$ ) when ozone is present depending on pH, due to reactions (13)–(15) where ozone needs  $1 e^-$  per  $\cdot OH$  formed, and the generation of  $H_2O_2$  from direct methanol ozonation (reaction (20)), that acts as an electron acceptor (reaction (6)) needs also  $1 e^-$  per  $\cdot OH$  formed. The maximum quantum yield at basic-neutral pH when  $O_3$  is present has not been accurately calculated since ozone-indirect reactions are closely related to the reactions involving photogenerated species. Thus, the calculated values seem to be reasonable although they should be taken with caution, especially that calculated at pH = 7 where the contribution of the indirect-ozone reaction has been taken as the same than in single ozonation and may be underestimated. Further work will be carried out to quantitatively calculate the different contributions through a detailed reaction mechanism for the AOPs studied (photocatalytic oxidation, ozonation and photocatalytic ozonation). Despite this it is clear that ozone exerts a positive

effect on the photocatalytic induced reactions (not only  $O_3$  direct and indirect reactions) due to two main factors: (i) ozone acts as an electron acceptor, (ii) hydrogen peroxide usually formed during direct ozonation reactions also acts as an electron acceptor, both leading to higher amount of hydroxyl radicals per photon absorbed and also reducing the recombination process to some extent.

### 3.2.4. Simplified economic considerations

In addition to the benefits observed with the combined treatment, i.e. photocatalytic ozonation ( $TiO_2/O_3/UVA$ ), in the reaction rate of formaldehyde formation, the synergistic effect between ozone and irradiated  $TiO_2$  and the highest quantum yield of photo-generated oxidizing species production, one important issue in the application of combined treatments is the economy of the process. Accordingly, to compare the different systems, costs associated with the normal operation have been evaluated by taking into account the oxygen and electrical energy consumed to generate the oxidants and/or radiation and the amount of formaldehyde formed. It has to be highlighted that this simplified economic study aims only the comparison of the systems (i.e. investments, loss of  $TiO_2$  activity and separation, and other factors are not considered) not providing an actual costs estimation.

According to Rivas et al. [45] for the same ozone generator, the dependence between  $O_3$  production and current consumption can be estimated as:

$$O_3(\% \text{ of max. flow rate in g L}^{-1}) = 186 \cdot \text{current consumption in A} \quad (23)$$

with maximum mass flow rate from oxygen  $12\text{ g h}^{-1}$ . From the experimental conditions for 10 and  $30\text{ mg L}^{-1} O_3$  at  $30\text{ L h}^{-1}$  those are 2.5% and 7.5% of the maximum amount produced, respectively. In photocatalytic experiments it is also necessary to take into account the lamps energy consumption (2 lamps with an input power of 15 W). The cost associated with electricity has been considered  $0.14\text{ € (kWh)}^{-1}$  according to the local supplier. In addition, in all the experiments oxygen from cylinders was used which has a cost of  $0.262\text{ € h}^{-1}$  [45] at a flow rate of  $30\text{ L h}^{-1}$ .

With the above data, Table 3 shows the results obtained to produce 0.001 mol of formaldehyde from methanol oxidation taking into account the time needed. It can be observed that the main contribution (of the considered) is the oxygen consumption. It has to be pointed out that this contribution would be far different if air from atmosphere was used both in photocatalytic oxidation and ozonation runs (in the latter two using an air compressor) since there are ozone generators able to work with air. The operation costs (as calculated here) are always higher in photocatalytic experiments or ozonation alone than in the combined process, especially when working at pH = 7, where the reaction time is highly reduced. Therefore, photocatalytic ozonation treatment is not only attractive from the point of view of their performance in terms of reaction rates but also in terms of economic considerations, where the synergism between ozone and  $TiO_2$  photocatalysis is also clear. However, it has to be emphasized that this

**Table 3**  
Estimated costs for the transformation of  $10^{-3}\text{ mol CH}_3\text{OH}$  (CHOH formed).

Process	pH	$C_{O_3,ginlet}$ (mg L <sup>-1</sup> )	Time used (h)	$E_{O_3}$ (kWh)	$E_{UVA}$ (kWh)	Electricity (€)	$O_2$ (€)	Cost/mmol converted (€ mmol <sup>-1</sup> )
Photocatalytic oxidation ( $TiO_2/O_2/UVA$ )	3	0	1.90	0	$5.70 \times 10^{-2}$	$7.98 \times 10^{-3}$	$4.97 \times 10^{-1}$	$5.05 \times 10^{-1}$
	7	0	2.22	0	$6.66 \times 10^{-2}$	$9.32 \times 10^{-3}$	$5.81 \times 10^{-1}$	$5.90 \times 10^{-1}$
Ozonation ( $O_3$ )	3	10	1.63	$4.83 \times 10^{-3}$	0	$6.76 \times 10^{-4}$	$4.27 \times 10^{-1}$	$4.28 \times 10^{-1}$
	7	30	0.11	$9.54 \times 10^{-4}$	0	$1.34 \times 10^{-4}$	$2.80 \times 10^{-2}$	$2.80 \times 10^{-2}$
Photocatalytic ozonation ( $TiO_2/O_3/UVA$ )	3	10	0.57	$1.69 \times 10^{-3}$	$1.72 \times 10^{-2}$	$2.64 \times 10^{-3}$	$1.50 \times 10^{-1}$	$1.52 \times 10^{-1}$
	7	30	0.07	$6.21 \times 10^{-4}$	$2.10 \times 10^{-3}$	$3.81 \times 10^{-4}$	$1.80 \times 10^{-2}$	$1.90 \times 10^{-2}$

simplified economic study could give different results in every particular case taking into account the necessities of effluent mineralization; discharge limits required; investment and replacement costs, etc. as reported before [45] where ozone treatments involved higher costs at the same mineralization degree obtained.

#### 4. Conclusions

Major conclusions reached in this study are:

- Absorbed light intensity during photocatalytic oxidation of methanol was indirectly calculated at different pH values and was always higher than 90% of that impinging the reactor for the catalyst loading used (0.5 g L<sup>-1</sup> of TiO<sub>2</sub> P25).
- The presence of ozone during photocatalytic ozonation at pH = 3 exerts a positive effect on the reaction rate of formaldehyde formation respect to photocatalytic oxidation. This was not only due to the direct ozone-methanol reaction, but also due to the reaction of dissolved ozone and hydrogen peroxide (formed upon CH<sub>3</sub>OH ozonation), electron acceptors to produce higher concentration of hydroxyl radicals.
- An increase in ozone concentration exert a positive but low effect during photocatalytic ozonation likely due to self-scavenging reactions between ·OH and ozone or hydrogen peroxide.
- The quantum yield calculated for photo-generated oxidizing species during photocatalytic oxidation at pH = 3 was  $\phi_{hv} = 0.34 \text{ mol einstein}^{-1}$ . This parameter was increased to around  $\phi_{hv} = 0.80 \text{ mol einstein}^{-1}$  when combining TiO<sub>2</sub>/O<sub>3</sub>/UVA. This enhancement was even higher at pH = 7 from  $\phi_{hv} = 0.29$  to  $\phi_{hv} = 3.27 \text{ mol einstein}^{-1}$ . Therefore, a clear synergism between ozone and black light photocatalytic oxidation with TiO<sub>2</sub> is pointed out due to the decrease of the recombination process. The reaction of dissolved ozone and hydrogen peroxide with photo-generated electrons is likely the reason of the reaction rate enhancement.
- Simplified economic evaluation taking into account only normal operation has shown that photocatalytic ozonation could be a cost-effective treatment depending on the actual necessities of the effluent to be treated.
